**A new tellurium-substituted Lindqvist-type polyoxoniobate [H<sub>2</sub>TeNb<sub>5</sub>O<sub>19</sub>]<sup>5-</sup> was synthesized as a tetramethylammonium salt. When irradiated with a Xe lamp, a water–methanol solution of this cluster showed exceptionally high H<sub>2</sub>-evolution activity suggesting cocatalysis by the hexaniobate cluster and metallic tellurium, both of which are formed as photodecomposition products.**

The most common aqueous complexes of Nb<sup>V</sup> are the hexaniobate Lindqvist ion (Nb<sub>6</sub>) and the decaniobate ion and these two clusters dominate in different pH regions.<sup>1</sup> Heterometal-substituted Lindqvist-type polyoxoniobate ions are virtually unknown and the single example is the tungsten-rich [HNb<sub>2</sub>W<sub>4</sub>O<sub>19</sub>]<sup>3-</sup> ion.<sup>2</sup> Herein we report a tellurium-monosubstituted Lindqvist-type polyoxoniobate ion as a tetramethylammonium (TMA) salt, TMA<sub>5</sub>[H<sub>2</sub>TeNb<sub>5</sub>O<sub>19</sub>]·20H<sub>2</sub>O (**1**). This molecule is important for two reasons, firstly because <sup>125</sup>Te is an NMR-active nucleus with spin 1/2 and a long relaxation time, allowing study of aqueous chemistry in ways that were difficult with the unsubstituted hexaniobate ion, wherein only <sup>17</sup>O NMR could be used as an NMR probe to solution chemistry,<sup>3</sup> and secondly because the molecule photodecomposes to a catalytic system for H<sub>2</sub> production, as shown in this study. Although the niobate Lindqvist ion is well known, its utility in the field of hydrogen energy is not well investigated. Here we demonstrated that Te-substitution of the Lindqvist ion can generate a highly active photocatalytic system in comparison to the pristine Lindqvist hexaniobate ion.

Tellurium substitution has been previously achieved in other polyoxometalate systems including Anderson-type [TeMo<sub>6</sub>O<sub>24</sub>]<sup>6-</sup> clusters, *trans*-disubstituted Lindqvist-type [Te<sub>2</sub>Mo<sub>4</sub>O<sub>19</sub>]<sup>6-</sup> clusters and decavanadate-type [HTeV<sub>9</sub>O<sub>28</sub>]<sup>4-</sup> clusters.<sup>4,5</sup> A mixed oxide of molybdenum, vanadium, tellurium and niobium has been shown to be a good catalyst for conversion of hydrocarbons; thus the tellurium-substituted niobate ion has potential to act as a catalytically active oxide precursor.<sup>4a,5a</sup> Solid niobates have also been studied as water-splitting photocatalysts, along with more effective and well-known titanates and tantalates,<sup>6</sup> as niobium oxides have a bandgap energy of about 3.4 eV and that compares well to ZnO or TiO<sub>2</sub>.<sup>7</sup> Photocatalytic H<sub>2</sub> evolution activities of oligomeric polyoxoniobates have been reported recently.<sup>8</sup>

The synthesis of **1** was carried out by a hydrothermal reaction of a mixture of Te(OH)<sub>6</sub> (telluric acid), hydrous niobium oxide and TMAOH. Electrospray-ionization mass spectrometry (ESI-MS) of the solution after reaction suggested the formation of a new Te-substituted cluster, as proven by the complex fingerprint of each peak due to the naturally occurring Te isotopes and higher *m/z* values compared to the TMA salt of hexaniobate, TMA<sub>5</sub>[H<sub>3</sub>Nb<sub>6</sub>O<sub>19</sub>]·20H<sub>2</sub>O (**2**) [Fig. S1, S4 and S5, ESI†]. The peak positions match well with calculated peaks of the TMA salt of Te-monosubstituted hexaniobate [Fig. S1, ESI†].

The structure of [H<sub>2</sub>TeNb<sub>5</sub>O<sub>19</sub>]<sup>5-</sup> (TeNb<sub>5</sub>) in **1** was determined by X-ray single crystallography [Fig. 1].‡ The tellurium substitution is obvious from the high electron density in one (Te1/Nb1 site) of the three crystallographically independent metal sites. Tellurium is disordered between the two opposite metal sites in the Lindqvist ion due to its centrosymmetry. Refinement with the partial occupancy model at the Te1/Nb1 site showed that the sum of tellurium occupancy in these two sites is 0.95, which is in good agreement with the suggested TeNb<sub>5</sub> stoichiometry. Two protons are bound on the two opposite μ<sub>2</sub>-O, linking Nb2 and Nb3 on the equatorial plane. Five TMA counteranions are found in the structure refinement, and the formula is expressed as TMA<sub>5</sub>[H<sub>2</sub>TeNb<sub>5</sub>O<sub>19</sub>]·20H<sub>2</sub>O. The cell constants are very similar to those of the previously reported **2**,<sup>9</sup> which is in agreement with the isostructural and isovalent Lindqvist-type cluster

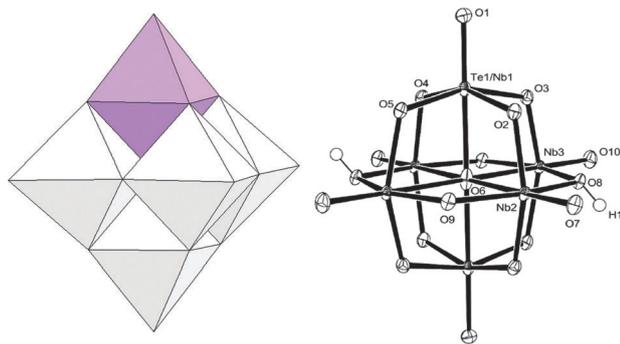

Fig. 1 Polyhedral model (left, Te<sup>VI</sup>: purple, Nb<sup>V</sup>: white) and thermal ellipsoid model of [H<sub>2</sub>TeNb<sub>5</sub>O<sub>13</sub>]<sup>5-</sup> (right). Unlabelled atoms are related to the labelled atoms by inversion symmetry.

crystallized with the same number of TMA counteractions and crystallization water. As a result of the substitution, the terminal Te/Nb–O<sub>t</sub> bond (1.8082(12) Å) is longer than the unsubstituted terminal Nb–O<sub>t</sub> bond in the periphery (1.7505(11) and 1.7727(11) Å). And the Te/Nb–μ<sub>6</sub>-O bond (2.28325(15) Å) is shorter than Nb–μ<sub>6</sub>-O bonds (2.41480(16) and 2.44065(15) Å). Because of the mixed metal occupancy, thermal ellipsoids of Te1/Nb1 and μ<sub>6</sub>-O are elongated in the axial direction [Fig. 1].

Solid-state <sup>125</sup>Te NMR experiment was performed to characterize the Te<sup>VI</sup> in the cluster. The single substitution in TeNb<sub>5</sub> suggests one peak. As predicted, solid-state <sup>125</sup>Te NMR spectrum shows one isotropic peak at 754 ppm accompanied with spinning sidebands [Fig. 2]. We note that the spinning sidebands are not symmetric about the central isotropic peak because Te is in an asymmetric structural environment. The Te is located at one metal site of the Lindqvist cluster, which is intrinsically asymmetric, and faces the center of the cluster on one side, while the other side is coordinated with the terminal oxygen atom and is closer to TMA ions and crystallization waters [Fig. 1, Fig. S2, ESI<sup>†</sup>].

The pH-dependent stabilities of **1** and **2** were examined by performing ESI-MS and UV-Vis titration experiments. ESI-MS spectra of 31 mM solution (pH = 8.1) of each compound were

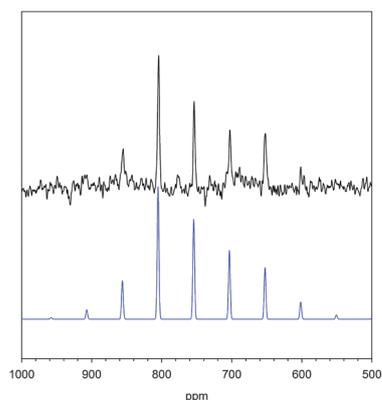

Fig. 2 The <sup>125</sup>Te MAS NMR spectrum (top) can be fitted with a CSA pattern at a spinning speed of 8 kHz (bottom). The axially of the CSA is –160 ppm, the asymmetry parameter is 0.56, the peak width is 300 Hz, and the isotropic chemical shift is 754.3 ppm. These parameters describe the local coordination environment of the Te<sup>VI</sup> site.

recorded after the addition of acid or base to modify the solution pH. The peaks of **1** only slightly decreased up to pH ~ 13 when titrated with base, indicating that the TeNb<sub>5</sub> cluster is stable under strongly basic conditions [Fig. S4, ESI<sup>†</sup>]. When titrated with acid, the solution became cloudy, and increasingly so, upon addition of each aliquot below pH 7, which was probably due to formation of hydrous niobium-oxide colloids. However, most of the clusters in solution had converted to colloidal particles at pH ~ 5 and below. ESI-MS titration of **2** showed similar behaviour [Fig. S5, ESI<sup>†</sup>]; Nb<sub>6</sub> was stable between 7 < pH < 12 but less stable under extreme pH conditions, as suggested by normalized abundance of representative peaks in ESI-MS depending on pH [Fig. S6, ESI<sup>†</sup>]. In the UV-Vis titration experiment using a more dilute solution (0.03 mM), the electronic spectra of **1** which show LMCT bands at 240 nm and small shoulder at 265 nm did not change significantly up to pH 12.5, which agrees with the stability of TeNb<sub>5</sub> under the basic conditions [Fig. S7, ESI<sup>†</sup>]. During the titration with acid, the overall absorption increased up to pH ~ 4, which is indicative of decomposition. A solution of **2** showed a similar trend in the UV-Vis titration [Fig. S8, ESI<sup>†</sup>].

We examined photochemical H<sub>2</sub> evolution from each 0.2 g of **1** and **2** in a water-methanol solution (25 mL, 80 : 20 v/v) under UV and visible light from a 300 W Xe lamp. Hydrogen evolution activity of TMA salt of peroxohexaniobate, TMA<sub>5</sub>[H<sub>3</sub>Nb<sub>6</sub>O<sub>13</sub>(O<sup>II</sup>)<sub>2</sub>]<sub>6</sub>·9.5H<sub>2</sub>O (**3**),<sup>9</sup> was also measured. Methanol was used as a sacrificial electron donor and H<sub>2</sub> was monitored by gas chromatography. Visible light (>400 nm) did not produce H<sub>2</sub>; however, under full Xe spectrum illumination a solution of **1** evolved H<sub>2</sub> at a rate of 776 μmol h<sup>-1</sup> g<sup>-1</sup>, which is 70 times higher than that of **2** (11 μmol h<sup>-1</sup> g<sup>-1</sup>) [Fig. 3]. Upon irradiation, the solution of **2** remained colorless while the solution of **1** became gradually darker and about 10 mg of a black precipitate formed after 8 hours, which was identified as metallic tellurium in mostly nanowire morphology mixed with some microcrystals, on the basis of SEM and XRD data (Fig. S9 and S10, ESI<sup>†</sup>). The formation of metallic tellurium indicates reduction of the Te<sup>VI</sup> in **1** to Te<sup>0</sup> as the cluster decomposed. The apparent chemical conversion of the niobate cluster is also reflected in the non-linear H<sub>2</sub> evolution plot, which shows an abrupt increase of activity after 2 h. The main product of the photo-assisted

Scheme 1 Proposed photocatalytic reaction mechanism.

conversion of **1–3** in the solution phase after irradiation was the Nb<sub>6</sub> ion, as detected by ESI-MS. The peroxohexaniobate ion **3** showed lowest H<sub>2</sub> evolution activity (1 μmol h<sup>-1</sup> g<sup>-1</sup>) when compared to **1** and **2**, but evolved small amounts of O<sub>2</sub> during irradiation, likely due to the photo-induced removal of the peroxo ligand.

The supernatant and precipitate were separated after irradiation of solution of **1** for 8 h to evaluate the H<sub>2</sub>-evolution activity of each photo-decomposition product separately. Te<sup>0</sup> wires alone showed very low H<sub>2</sub> evolution activity when mixed with water-methanol [Fig. 3]. The separated supernatant continued to form more Te<sup>0</sup> upon irradiation due to the small amount of tellurate present in the supernatant. This supernatant showed a similar H<sub>2</sub> evolution curve but lower H<sub>2</sub> evolution activity than the original solution [Fig. 3] probably due to the smaller amount of precipitate, suggesting that coexistence of the niobate cluster and metallic Te<sup>0</sup> is necessary to maintain the high H<sub>2</sub> evolution activity.

These results suggest a mechanism for photocatalytic H<sub>2</sub> evolution shown in Scheme 1. Photoexcitation of TeNb<sub>5</sub> forms an electron-hole pair and the electron reduces Te<sup>VI</sup> in the cluster. As a result, TeNb<sub>5</sub> is decomposed to Te<sup>0</sup> and Nb<sub>6</sub> with the hole oxidizing methanol as a sacrificial electron donor, ultimately forming CO<sub>2</sub> and H<sub>2</sub>O. Once Te<sup>VI</sup> is fully reduced to Te<sup>0</sup>, it may further accept electrons to become telluride (Te<sup>2-</sup>). We speculate that this aqueous telluride will reduce protons to evolve H<sub>2</sub>, as H<sub>2</sub>Te has been shown to decompose to metallic tellurium in aqueous solution.<sup>10</sup> Thus we believe that the high H<sub>2</sub> evolution activity in this system is due to coexistence of Nb<sub>6</sub> and Te<sup>0</sup> nanowires or colloids and that the native tellurium metal acts as a H<sub>2</sub>-evolution cocatalyst. Cobaloxime or H<sub>2</sub>PtCl<sub>6</sub> has been commonly used as a cocatalyst in the study of H<sub>2</sub> evolution from polyoxoniobate and many other systems.<sup>6c,8</sup> To our knowledge, this is the first demonstration of Te<sup>0</sup> as a H<sub>2</sub> evolution cocatalyst.

For control experiments, stoichiometric mixtures of telluric acid and **2** (Te:Nb = 1:5) were tested for H<sub>2</sub> evolution. Nearly the same amount (~10 mg) of Te<sup>0</sup> formed in this solution after irradiation, but the amount of H<sub>2</sub> evolved (71 μmol h<sup>-1</sup> g<sup>-1</sup>) was about an order of magnitude smaller than that produced from the solution of **1**, but higher than that produced from the solution of **2** alone [Fig. 3]. This result implies that the reduction of Te<sup>VI</sup> in TeNb<sub>5</sub> can occur directly within the cluster from the photogenerated electron-hole pairs, in such a way that formation of metallic tellurium in the solution of **1** is faster than in the simple solution mixture of telluric acid and **2**. This explains the high H<sub>2</sub> evolution rate in the early stage of

irradiation of **1** compared to the control experiment. The total surface area of the particles in the solution of **1** might also be higher than that in the mixture of telluric acid and **2** because of the faster formation of particles, which might have resulted in the high H<sub>2</sub>-evolution activity.

In conclusion, the TMA salt of the TeNb<sub>5</sub> molecule reported herein exhibits a similar pH stability window and solid-state structure compared to Nb<sub>6</sub>, but demonstrates much higher H<sub>2</sub>-evolution activity *via* a photo-decomposition route to Nb<sub>6</sub> and Te<sup>0</sup> nanowires. Future studies shall focus on the hydrolysis and isotope-exchange kinetics of the TeNb<sub>5</sub> molecule, by using <sup>17</sup>O and <sup>125</sup>Te NMR together, and compare hydrolysis chemistry with that of the unsubstituted Nb<sub>6</sub>.
