DOI: 10.1039/c1ee02110a

Alpha-Fe$_2$O$_3$ is cheap and abundant, and has a visible light indirect (phonon assisted) band gap of 2.06 eV (600 nm) due to a d–d transition, and a direct band gap at 3.3 eV (375 nm), associated with the ligand to metal charge transfer process. Here we describe results on using freely dispersed Fe$_2$O$_3$ nanocrystals for photocatalytic water oxidation. Three morphologies of hematite were compared, including bulk-type-ß-Fe$_2$O$_3$ (Bulk-Fe$_2$O$_3$, 120 nm), ultrasonicated Bulk-Fe$_2$O$_3$ (Sonic-Fe$_2$O$_3$, 44 nm), and synthetic Fe$_2$O$_3$ (Nano-Fe$_2$O$_3$, 5.4 nm) obtained by hydrolysis of FeCl$_3$·6H$_2$O. According to X-ray diffraction, all phases were presented in the alpha structure type, with Nano-Fe$_2$O$_3$ also containing traces of ß-FeOOH. UV/Vis diffuse reflectance revealed an absorption edge near 600 nm ($E_G = 2.06$ eV) for all materials. Cyclic voltammetry gave the water oxidation overpotentials ($versus$ NHE at pH 7, at 1.0 mA cm$^{-2}$) as $\eta = +0.43$ V for Nano-Fe$_2$O$_3$, $\eta = +0.63$ V for Sonic-Fe$_2$O$_3$, and $\eta = +0.72$ V for Bulk-Fe$_2$O$_3$. Under UV and visible irradiation from a 300 W Xe-arc lamp, all three materials (5.6 mg) evolved O$_2$ from water with 20.0 mM aqueous AgNO$_3$ as sacrificial electron acceptor. The highest rates were obtained under UV/Vis (>250 nm) irradiation with 250 $\mu$mol h$^{-1}$ g$^{-1}$ for Bulk-Fe$_2$O$_3$, 381 $\mu$mol h$^{-1}$ g$^{-1}$ for Sonic-Fe$_2$O$_3$ and 1072 $\mu$mol h$^{-1}$ g$^{-1}$ for Nano-Fe$_2$O$_3$. Turnover numbers (TON = moles O$_2$/ moles Fe$_2$O$_3$) were above unity for Nano-Fe$_2$O$_3$ (1.13) and Sonic-Fe$_2$O$_3$ (1.10) but not for Bulk-Fe$_2$O$_3$ (0.49), showing that the nanoscale morphology was beneficial for catalytic activity.

Introduction

Given the growing global demand for energy, one of the most important challenges of the century will likely involve developing a cheap and active material for solar water splitting. Currently, however, no economically competitive water-splitting photocatalysts have been marketed mainly due to low overall conversion efficiencies and photocorrosion. Nano-scaling of bulk metal-oxide/sulphide/selenides offers new opportunities to develop more efficient catalysts, by taking advantage of increased surface area, shorter paths for charge and mass transport, and quantum confinement effects. Cadmium selenide, for example, can be activated for photocatalytic water reduction using a quantum size effect. Iron oxide (ß-Fe$_2$O$_3$, hematite) is an attractive candidate for photocatalytic water oxidation, due to its low cost,

Broader context

Nanostructured alpha-Fe$_2$O$_3$ (hematite) has recently emerged as an inexpensive and stable photoanode material for photoelectrochemical water oxidation. Such photoanodes help facilitate direct sunlight driven water photoelectrolysis by which solar energy is converted into hydrogen fuel. The enhanced properties of nano-Fe$_2$O$_3$ are generally attributed to improved hole collection at the surface, enabled by the reduced dimensions of the nanocrystals. However, one can not rule out that part of the enhancement stems from impurity atoms such as silicon and tin which are introduced during the preparation of the photoanodes. Here we show for the first time, that photocatalytic water oxidation can be achieved also with suspended hematite particles, in the absence of any dopants. We find that the activity of the particles scales inversely with size, and that it is limited by deposition of silver onto the particles—a side effect of using silver nitrate as sacrificial electron acceptor. Even though the quantum efficiency remains below 1.0% for the smallest studied nanocrystals, the results highlight the validity of the nanoscaling approach for increasing photocatalytic activity in materials with short minority carrier lifetimes.
abundance, low toxicity, high photo/heat-stability, suitable band gap \( (E_g = 2.06 \text{ eV}, \lambda = 600 \text{ nm}) \) and valance band edge position. Despite these attributes, however, \( \alpha \)-Fe\(_2\)O\(_3\) is considered to be a poor photo-anode material for water oxidation due to its short hole diffusion length (2–4 nm),\(^4,5\) short exciton lifetime (~10 ps),\(^4,5\) poor minority charge carrier mobility (0.2 cm\(^2\)V\(^{-1}\)s\(^{-1}\)),\(^6\) and finite light penetration depth (\( \alpha \sim 118 \text{ nm at } \lambda = 550 \text{ nm} \)).\(^7\) Attempts to circumnavigate these issues involve a combination of surface modifications to reduce water oxidation overpotentials along with surface morphology control to increase current density.\(^8\) This includes selective growth of thin films on the most active crystal face (001) for more efficient electron and hole transport,\(^9\) and doping with metal cations including Mg\(^{2+}\), Al\(^{3+}\), Ca\(^{2+}\), Ti\(^{4+}\), V\(^{5+}\), Cu\(^{2+}\), Zn\(^{2+}\), Nb\(^{5+}\), Sn\(^{4+}\), Pt\(^{4+}\), and CO\(_2\).\(^10\) Another approach to mitigate these problems is by nanostructuring Fe\(_2\)O\(_3\). Kay \textit{et al.} demonstrated that nanostructured Fe\(_2\)O\(_3\) films grown by vapor deposition of Fe(CO)\(_5\)/tetraethoxysilane could support photocurrent densities of up to 2.2 mA cm\(^{-2}\) and incident photon to electron conversion efficiencies (IPCEs) of up to 42% at 1.23 eV vs. RHE.\(^9\) In another example, Fe\(_2\)O\(_3\) photoelectrodes were fabricated from Fe\(_2\)O\(_3\) nanocrystals, followed by an annealing step.\(^10\) These electrodes showed increased water oxidation activity, but also contained Si and Pt dopants that lead to increased conductivity. Similar Fe\(_2\)O\(_3\) electrodes have been fabricated from Fe\(_2\)O\(_4\) particles followed by annealing.\(^16\) To evaluate the effect of nanostructuring in the absence of doping, we report here on photocatalytic water oxidation with suspended bulk and nanoparticulate \( \alpha \)-Fe\(_2\)O\(_3\). The study shows for the first time, that individually suspended Fe\(_2\)O\(_3\) particles catalyze water oxidation with up to 0.61% quantum efficiency (at 375 nm) in the presence of a chemical bias (+0.70 V, NHE from 20.0 mM AgNO\(_3\)). The activity is inversely dependent on particle size, which we attribute to improved charge transport to the surface in the smaller particles. We also find that chemically synthesized particles have a significantly lower electrochemical overpotential for water oxidation than particles derived from bulk Fe\(_2\)O\(_3\).

### Results and discussion

Scheme 1 summarizes pathways to Nano-Fe\(_2\)O\(_3\) [1], Sonic-Fe\(_2\)O\(_3\) [2], and Bulk-Fe\(_2\)O\(_3\) [3] as photocatalysts for this study. Suspensions of Bulk-Fe\(_2\)O\(_3\) were produced by briefly (5 s) sonication of commercial alpha-Fe\(_2\)O\(_3\) (hematite) in water. To obtain nanoscale materials, Fe\(_2\)O\(_3\) was sonicated at a higher intensity for 30 min. As an alternative to this top-down approach, Nano-Fe\(_2\)O\(_3\) was prepared from FeCl\(_3\) in aqueous HCl using the published procedure by Raming \textit{et al.} \(^19\)

**Scheme 1** Bottom-up approach to give Nano-Fe\(_2\)O\(_3\) [1] and top-down approach to prepare Sonic-Fe\(_2\)O\(_3\) [2] from Bulk-Fe\(_2\)O\(_3\) [3]. Sonication was performed with an ultrasonic horn at 3.65 W.

Fig. 1 shows the powder XRD spectra of the three samples. For Bulk-Fe\(_2\)O\(_3\) and Sonic-Fe\(_2\)O\(_3\), all diffraction peaks can be assigned to the alpha phase of hematite. Due to lattice confinement, the Nano-Fe\(_2\)O\(_3\) diffraction pattern consists of wider peaks and larger Full width at half maximum (FWHM) including an unexpected peak at 47° signifying the presence of \( \beta \)-FeOOH (411 peak),\(^20\) a known intermediate during aqueous synthesis of hematite.\(^21\) From the FWHM values of the (113) diffraction peak at 40°, Scherrer diameters were calculated as 120 nm for Bulk-Fe\(_2\)O\(_3\), 44 nm for Sonic-Fe\(_2\)O\(_3\), and 5.4 nm for Nano-Fe\(_2\)O\(_3\). These values are in good agreement with data obtained from transmission electron microscopy in Fig. 2.

According to TEM/HRTEM, Bulk-Fe\(_2\)O\(_3\) consists of large irregular and polydispersed (50–300 nm) crystals showing characteristic (001) lattice spacing of \( \alpha \)-Fe\(_2\)O\(_3\) (Fig. 2a, b). Comparatively, Sonic-Fe\(_2\)O\(_3\) shows smaller (5–20 nm) fragmented particles with irregular shapes, and lesser defined surfaces (Fig. 2e, f). In contrast, Nano-Fe\(_2\)O\(_3\) images display a range of single crystalline spheres (5.2 ± 1.0 nm) interdispersed with rods (5.0 ± 0.8 nm × 15.2 ± 1.1 nm, Fig. 2i, j).

Diffuse reflectance spectra for the three materials are shown in Fig. 3 and plotted with the Kubelka-Munk function. The band edge at 600 nm corresponds to a 2.06 eV band gap for each material. There is also a direct UV transition LMCT at 375 nm peak (6t1u → 2t2g, 375 nm, not shown) and an indirect visible d–d transition (\( \Delta_1 \) → \( \Delta_E \), 535 nm). This d–d transition is slightly blue shifted for Nano-Fe\(_2\)O\(_3\) which accounts for the observed differences in color: Bulk-Fe\(_2\)O\(_3\) (light red/orange), Sonic-Fe\(_2\)O\(_3\) (pink/orange), and Nano-Fe\(_2\)O\(_3\) (dark blood red, orange when diluted). The difference in slope between Nano-Fe\(_2\)O\(_3\) and the other two is likely caused by the presence of small amounts of \( \beta \)-FeOOH in the sample (a yellow precursor to \( \alpha \)-Fe\(_2\)O\(_3\), \( E_g = 2.12–2.35 \text{ eV} \)).\(^20\) The plot also shows a characteristic sub-band...
scattering tail near 600–750 nm. The scattering intensity of this tail is known to increase with particle size.\textsuperscript{17}

To test photocatalytic properties, the Fe\textsubscript{2}O\textsubscript{3} powders were suspended in 20.0 mM aqueous AgNO\textsubscript{3} and irradiated with a 300 W Xe-arc lamp equipped with a longpass filter (>400 nm) or without it (>250 nm). Under these conditions, oxygen is formed from photogenerated holes (Fig. 5) while silver is formed from photogenerated electrons. The deposition of silver can be seen in Fig. 2(e–h) and Fig. 3(i–l). Figure 3 shows the Kubelka-Munk converted UV/Vis diffuse reflectance spectra of dried Bulk-Fe\textsubscript{2}O\textsubscript{3}, Sonic-Fe\textsubscript{2}O\textsubscript{3} and Nano-Fe\textsubscript{2}O\textsubscript{3} catalysts.

Fig. 2 TEM (a,c,e) and HRTEM of non-irradiated \(\alpha\)-Fe\textsubscript{2}O\textsubscript{3} (a,b,c,f,i,j) and after full-spectrum AgNO\textsubscript{3} irradiation (c,d,g,h,k,l). Bulk-Fe\textsubscript{2}O\textsubscript{3} (a–d), Sonic-Fe\textsubscript{2}O\textsubscript{3} (e–h), and Nano-Fe\textsubscript{2}O\textsubscript{3} (i–l). Image g is not representative of particle size. It was chosen to demonstrate silver particle formation.

Fig. 3 Kubelka-Munk converted UV/Vis diffuse reflectance spectra of dried Bulk-Fe\textsubscript{2}O\textsubscript{3}, Sonic-Fe\textsubscript{2}O\textsubscript{3} and Nano-Fe\textsubscript{2}O\textsubscript{3} catalysts.

Fig. 5 Electrochemical water oxidation with Fe\textsubscript{2}O\textsubscript{3} films on Au substrate, 50 mV/s scans, at pH 7 in Na\textsubscript{2}HPO\textsubscript{4}/NaH\textsubscript{2}PO\textsubscript{4} buffer.
observed in TEMs of the Fe₂O₃ particles. Images for post-irradiated Bulk-Fe₂O₃ (Fig. 2c and 2d) show the 0.2 nm characteristic lattice spacing of Ag (011). In Fig. 2g, Ag deposition is not as clear for Sonic-Fe₂O₃ due to the small size, except that the overall solution color became darker and greyer after irradiation. One Ag particle on Sonic-Fe₂O₃ is shown in Fig. 2h. Likewise, Nano-Fe₂O₃ shows evidence of silver deposition onto the nanocrystals. Here, we observe preferential deposition onto one facet, most likely the (001) facet, which can be explained by a higher anisotropic conductivity in this direction.⁹ Notably, the material retains its crystallinity after 24 h full spectrum irradiation (Fig. 2i) with no signs of photocorrosion (apart from Ag deposition).

Comparing photoactivity among samples and conditions, the highest O₂ evolution rates are obtained under full spectral irradiation (>250 nm, Fig. 4A). During the first 10 min, evolution rates range from 250 μmol h⁻¹ g⁻¹ (for Bulk-Fe₂O₃) to 1071 μmol h⁻¹ g⁻¹ (for Nano-Fe₂O₃). However, with the advent of silver deposition, O₂ evolution begins to decline. For Bulk-Fe₂O₃ this happens after 8 h, for Sonic-Fe₂O₃ after 10 h, and for Nano-Fe₂O₃ after 5 h. After 24 h, turnover numbers (TON = moles of O₂ evolved per mole of Fe₂O₃) reach values above unity (1.13 for Nano-Fe₂O₃, 1.10 for Sonic-Fe₂O₃ and 0.49 for Bulk-Fe₂O₃), supporting a catalytic process for the nanomaterials. Apart from silver deposition, no change of the Fe₂O₃ is apparent (Fig. 2). This suggests that higher turnover numbers should be possible with other sacrificial agents. Under visible irradiation (>400 nm, Fig. 4B) the rates are notably lower, and as a consequence, TON numbers after 24 h (0.73 for Nano-Fe₂O₃, 0.38 for Sonic-Fe₂O₃ and 0.08 for Bulk-Fe₂O₃) remain below unity. The lower activity under visible illumination is expected from both the lower absorbance of the material and from the less oxidizing power of holes created in the Fe-t₂g band (see discussion of Fig. 6).

The initial O₂ evolution rates of the three systems are plotted in Fig. 4C as a function of size. It can be seen that for both visible and UV irradiation, the rate increase is inversely proportional to the logarithm of particle diameter. For visible light (λ > 400 nm), the slope is lower, because of the reliance of the photoreaction on the weaker d–d transition (see discussion of Fig. 6). Also, visible light penetrates deeper into the particles than UV light, reducing illumination-based differences among particles of different size. Improved illumination under visible light might be responsible for the high initial activity (first two hours) of Sonic-Fe₂O₃ that rivals that of Nano-Fe₂O₃ (Fig. 4B). However, as particle shading increases with silver deposition, the activity of the larger Sonic-Fe₂O₃ particles falls behind that of the smaller Nano-Fe₂O₃. Although shading effects do seem to play a role in these systems, the observed size trend in the activity of the Fe₂O₃ samples can be understood well in terms of the short hole diffusion length (2–4 nm)³ of hematite. Only holes generated within a 3 nm thick subsurface shell can participate in water oxidation. By comparing the volume of this shell in each sample with the total volume of the particles (assuming spheres), one can calculate the fraction of usable e/h pairs as a function of size (diameters taken from powder X-ray diffraction). The values are 14.3% for Bulk-Fe₂O₃, 35.6% for Sonic-Fe₂O₃, and 100% for Nano-Fe₂O₃—since it is less than 6 nm wide. This increased hole availability at the surface of the smaller particles can fully explain the observed trend in oxygen evolution across the series (Fig. 4). However, as additional irradiations with monochromatic light from a LED (375 nm) show, the fraction of holes that actually oxidize water is much lower than the number of holes created within 3 nm of the surface. Based on the observed O₂ generation rates under LED illumination (1.13 × 10⁻⁷ mol s⁻¹ at the flask surface), we calculate quantum efficiencies (QE) of 0.61%, 0.47%, and 0.0% for Nano-, Sonic-, and Bulk-Fe₂O₃, respectively. Here we assume that four photons/holes are required to form one molecule of O₂. The numbers show that even in Nano-Fe₂O₃, >97% of the generated charge carriers recombine before they react with water. This demonstrates that the reactivity of the nanocrystals is still limited by charge recombination (the half life of e/h pairs in hematite is ~10 ps).⁴ The problem of enhanced surface recombination in Fe₂O₃ is well known.²⁴ Surface recombination can be reduced by terminating...
Fe₂O₃ particles have a rough surface dominated by high index terraces on the surface with closed shell ions (Al³⁺, Sn⁴⁺, Si⁴⁺), as several research groups have shown recently.¹²,¹⁶,²⁵

In order to further probe the differences in reactivity between the Fe₂O₃ samples, electrochemical measurements were conducted on thin films of the materials. The voltammetric scans in Fig. 5 show that the electrochemical onset potentials for water oxidation are different for each particle size, with onsets occurring between +1.25 and +1.40 V (NHE, 1.0 mA cm⁻²). Based on the thermodynamic minimum water oxidation potential of +0.82 V vs. NHE at pH 7, the overpotentials (measured at 1.0 mA cm⁻²) are η = +0.43 V (Nano-Fe₂O₃), η = +0.63 V (Sonic-Fe₂O₃), and η = +0.72 V (Bulk-Fe₂O₃), respectively. This data is comparable to values published in the literature for alpha-Fe₂O₃ films (+0.57 V¹⁸ and +0.47 V¹⁹) after adjustment to pH = 7. This difference in potentials between Sono- and Nano-Fe₂O₃ is likely due to differences in surface structure. As a product of cavitation-induced particle fragmentation,²⁶ Sonic-Fe₂O₃ particles have a rough surface dominated by high index planes. This can be seen well in Fig. 2h. Nano-Fe₂O₃ on the other hand, is a product of strain-free growth, which favors the formation of stable low index facets. The effect of the surface structure on the reactivity of hematite nanocrystals was observed previously by Hermanek et al.²⁷

Fig. 6 shows potential diagrams for hematite nanocrystals was observed previously by Hermanek et al.²⁷

The diagram further shows that the oxygen evolution requires an electrochemical bias (about +0.70 V for 20.0 mM AgNO₃ at pH = 7), higher than what has been described for nanostructured α-Fe₂O₃ photoanodes (+0.39 V, NHE at pH 7).¹⁰ Thus, the thermodynamic driving force for electron transfer from the Fe₂O₃ conduction band edge to the silver ion acceptor is 0.30 eV per electron. Because the silver reduction potential of 0.70 V is less than the water oxidation potential (0.82 V at pH = 7), conversion of a fraction of the light energy into chemical energy is observed (0.12 eV per converted photon). However, because the quantum yield is so small (less than 1%), the overall process remains strongly exergonic.

Conclusion

In conclusion, we have shown that suspended crystals of non-doped alpha-Fe₂O₃ are active for photocatalytic O₂ evolution under visible and UV light with initial rates of up to 1072 μmol h⁻¹ g⁻¹ for Nano-Fe₂O₃. Under visible light the activity is 767 μmol h⁻¹ g⁻¹. Even though silver surface deposition limits the water oxidation ability of the materials, turnover numbers above unity were achieved for nanocrystals of Fe₂O₃, but not for the bulk. Activity is correlated inversely with the size of the crystals, i.e. Nano-Fe₂O₃ is more active than Bulk-Fe₂O₃, which can be explained with a reduced hole diffusion path to the surface. However as the low quantum efficiencies of 0.61% show, activities in all three systems are limited strongly by surface charge recombination. Also, we find that Nano-Fe₂O₃ crystals have a low water oxidation overpotential of 0.43 V (at 1.0 mA cm⁻²), which we attribute to a favorable surface structure of the material. This is the first time that direct catalytic O₂ generation from Fe₂O₃ was achieved via UV and visible light irradiation in homogeneous phase. The results show that nanoscaling increases the photoactivity of Fe₂O₃. Similar nanoscaling strategies may be applicable to other transition metal oxides.

Experimental

Chemicals (α-Fe₂O₃ 99.9%, AgNO₃ 99.9%, FeCl₃·6H₂O 99.9%, and 12.1 N HCl 99.99%) were purchased from Fisher Scientific, Pittsburg, PA. They were of reagent quality and were used as received. Water was purified to 18 MΩcm resistivity using a Nano-pure system. Bulk-Fe₂O₃ was prepared with as-prepared α-Fe₂O₃ and dissolved in water followed by 5 s sonication with a Fisher Scientific FS20 ultrasonic cleaner to disperse the colloid. Sonic-Fe₂O₃ was prepared by ultrasoninating Bulk-Fe₂O₃ for 30 min with a Sonics VibraCell™ VCX130 ultrasonic horn at 20% power (3.65 W) in 30 mL of H₂O. Nano-Fe₂O₃ was synthesized following a literature method²⁸ by dissolving FeCl₃·6H₂O into 250 mL of 0.002 M HCl at 100 °C to make a 0.02 M Fe³⁺ solution with stirring. After maintaining the temperature for 30 min, the heat was removed and the solution was allowed to return to room temperature. Excess spectator ions (Fe²⁺, H⁺ and Cl⁻, etc.) were removed during a 5 day dialysis using 6–8 k MWCO tubing in 4 L water. The water was replaced daily until the conductivity reached 4.0 μS cm⁻¹. Full chloride removal is important during this step to avoid formation of photoactive AgCl during irradiation.³⁰ The
final suspension contained 1.12 mg mL\(^{-1}\) of Fe\(_2\)O\(_3\) as determined by gravimetric analysis.

Transmission electron images were taken with a Philips CM-12 instrument at 120 kV acceleration potential. Bright field high resolution transmission electron microscopy (HRTEM) images were taken using a JEOL 2500SE 200kV TEM. Copper grids with a carbon film were dropped into aqueous dispersions of the samples followed by washing with water and air drying.

UV/Vis diffuse reflectance spectra were taken as dried powders on white Teflon tape using an Ocean Optics HR2000 CG-UVNIR spectrometer and a DH2000 light source. Reflectance was converted to Kubelka-Munk as \(f(R) = (1 - R)^2/(2R)\) vs. wavelength to correct for scattering.

For electrochemical measurements thin films of the catalysts were prepared on a gold foil electrode (1.0 cm\(^2\)) by dropcoating UVNIR spectrometer and a DH2000 light source. Reflectance on white Teflon tape using an Ocean Optics HR2000 CG-UVNIR spectrometer and a DH2000 light source. Reflectance was converted to Kubelka-Munk as \(f(R) = (1 - R)^2/(2R)\) vs. wavelength to correct for scattering.

The rate of photochemical oxygen evolution from each catalyst was determined by irradiating 5.6 mg (35 \(\mu\)mol) of Fe\(_2\)O\(_3\) in 20.0 mM AgNO\(_3\) in 50 mL of water. Silver nitrate was chosen as a sacrificial agent because it is stable under UV irradiation and does not cause aggregation of the nanoparticles (as observed with ferric nitrate, cerium (IV) ammonium nitrate, sodium iodate, and sodium persulfate). Irradiations were performed in a quartz round bottom flask with a 300 W Xe arc lamp (1.4 W cm\(^{-2}\) at flask, \(\lambda = 250–680\) nm), measured with a UV/Vis GaAsP photodetector. Visible light (\(\lambda > 400\) nm) was achieved by inserting a 400 nm long-pass filter between the light and the flask. The air-tight irradiation system connects a vacuum pump and a gas chromatograph (Varian 3800) with the sample flask to quantify the amount of gas evolved, using area counts of the peaks and the identity of the gas from the calibrated carrier times. Prior to irradiation, the flask was evacuated down to 5 torr and purged with argon gas. This cycle was repeated until the chromatogram of the atmosphere above the solution indicated that the sample did not contain hydrogen, oxygen, or nitrogen. A solution of 20.0 mM AgNO\(_3\) was tested as a control under full spectrum irradiation, and less than 3 \(\mu\)mol of O\(_2\) were evolved after 10 h. Quantum efficiency measurements were conducted with a 375 nm LED (3.42 mW cm\(^{-2}\)) in place of the lamps.

Powder XRD scans were conducted with a Scintag XRD, \(\lambda = 0.154\) nm at \(-45\) kV and 40 mA with tube slit divergence(2 mm), scatter(4 mm), column scatter(0.5 mm), and receiving(0.2 mm). The FWHM of the peaks were calculated with ThermoARL DMSNT software (version 1.39-1).
